ABSTRACT

µ-Benzene-1,2,4,5-tetracarboxylato-κ²O¹,O⁴⁸bis-[aqua-bis-2-(aminomethyl) pyridine-κ²N,N'] nickel (II) decahydrate, [Ni₄(amp)₂btc](H₂O)₉·10H₂O has been synthesized and its crystal structure determined by X-ray diffraction. The complex crystallizes in the Monoclinic space group P2₁/n with cell dimensions a= 11.0102 (10) Å, b= 21.5416 (19) Å, c= 11.0445 (10) Å and β= 118.753 (1)°, and two formula units per cell (Z= 2, Z'= 0.5).

The structure consists of centrosymmetric dimeric units in which the benzene tetracarboxylate anions (btc) bridge the symmetry-related nickel (II) cations, two bidentate chelating molecules of 2-(aminomethyl) pyridine and a terminal aqua ligand completing the six-fold coordination at each metal. These dimers link to each other via H-bonding to form chains parallel to [100], while the water solvates form a strongly bound 2D network parallel to (100), made up by small (R²(40)) and large (R²(8)) rings, the latter ones “pierced” by the chains of dimmers, with a profuse H-bonding interconnection between both substructures.

Magnetic susceptibility measurements as a function of temperature disclose weak interdimeric exchange interactions. Fitting of these data to a dimeric model yields J= -3.5 cm⁻¹ and g= 2.13.

Keywords: crystal structure, nickel complex, magnetism.

I. INTRODUCTION

Coordination chemistry is one of the most important and active research areas in Inorganic Chemistry. This interest can not only be explained by the different crystal structures and spatial arrangements presented by the coordination compounds, but also by the different properties exhibited by such compounds (magnetic, optical, electronic, etc.) and their applications in various fields [1-4].

In the formulation of coordination compounds the metal center plays an important role, and also the ligands. From the structural point of view, the multicarboxylate ligands are extremely interesting due to the different dimensions and topologies they can produce in the resulting compounds. One example is the benzene-1,2,4,5-tetracarboxylic acid, presenting eight possible active sites available for coordination and a variety of modes of union, either bridging, chelating or a mixture of both, due to the large degree of rotational freedom of its four carboxylate groups [5-8].

Regarding magnetism, some common features linking structure and magnetic behavior have been relatively well established over the years, mainly when the carboxylate acts in a bridging mode, viz., complexes that present monoatomic or syn-anti bridges (Scheme 1) which usually show weak antiferromagnetic interactions, in contrast with those in which the carboxylate bridge is in a syn-syn form, where the interaction is mostly strong and antiferromagnetic. On the other hand, anti-anti modes are not so determinant, as they may produce either ferro- or antiferromagnetic coupling [9-12].

Pursuing our interest in the correlation of structural and magnetic properties of transition metal complexes, we have prepared a new dimeric Ni(II) complex with 2-(aminomethyl) pyridine (amp) and benzene-1,2,4,5-tetracarboxylic acid (H₄btc), formulated as [Ni₄(amp)₂btc](H₂O)₉·10H₂O (1), (Scheme 2), where the link between metal centres does not go through either of the bridging types presented in Scheme 1, but runs instead through the whole btc intradimeric ligand, leaving both Ni(II) centres aside, at a rather large distance for any significant magnetic interaction. Our analysis will show, however, that some relevant magnetic properties may arise in spite of this seemingly unfavourable geometry, mainly due to the profuse interdimeric H-bonding network present.

2. EXPERIMENTAL

2.1. Materials
All reagents and solvents employed were commercially available and used as received without further purification.

2.2. Synthesis
For the synthesis of complex (1), benzene-1,2,4,5-tetracarboxylic acid (H$_4$btc; 0.254 g, 1 mmol) was slowly added to an aqueous solution (20 mL) of NaOH (0.16 g, 4 mmol). Nickel acetate tetrahydrate (0.497 g, 2 mmol) was dissolved in water (20 mL) and added to the above solution. The resulting mixture was stirred for 10 min, followed by the addition of a methanolic solution (15 mL) of 2-(aminomethyl)pyridine (amp: 206 µL, 2 mmol) and the mixture was refluxed for 4 h and then cooled to room temperature.

Single crystals of (1), suitable for X-ray diffraction studies, were obtained by slow solvent evaporation.

2.3. Crystallography
The X-ray diffraction data set was collected up to a 2θ max of 58° using monochromatic Mo Kα radiation, λ = 0.71073 Å, θ = 150 K on a Bruker Smart diffractometer. The following softwares were used in different stages of the crystal structure analysis process:

- Data collection: SMART; cell refinement: SAINT; data reduction: SAINT; program(s) used to solve structure: SHELXS97; program(s) used to refine structure: SHELXL2014/6; Molecular graphics: SHELXTL; software used to prepare material for publication: SHELXTL [13-16].

Crystal data, data collection and structure refinement details are summarized in Table 1. Crystalline data, data collection and structure refinement details are summarized in Table 1.

2.4. Magnetic measurements
Magnetic susceptibility measurements were performed in the temperature range 2-300 K, using a Quantum Design MPMS XL5 SQUID Susceptometer, with an applied field of 1000 Oe. Measurements were performed on a powder sample of (1) encapsulated in a gelatin container. The magnetic data were corrected for the diamagnetism of the constituent atoms from the Pascal’s constants [17].

3. Results and discussion
Crystal data, data collection and structure refinement details for the [Ni$_2$(amp)$_2$] (btc)$_2$(H$_2$O)$_2$ complex, where amp is 2-amino-methyl-pyridine and btc = Benzene-1,2,4,5-tetracarboxylate anion, are summarized in Table 1. Table 2 provides a selection of coordination parameters while Table 3 shows the most significant H-bonding interactions in the structure.

Symmetry codes: (i) x, -y+1, -z; (ii) x+1/2, -y+1/2, z-1/2; (iii) -x+2, -y, -z; (iv) x+3/2, -y+1/2, z+1/2; (v) x-1/2, -y+1/2, z+1/2; (vi) -x+1, -y, -z; (vii) -x+3/2, y+1/2, -z+1/2.
The binuclear complex (Fig. 1) crystallizes in P 2_1/n with Z = 1/2, and consists of two centrosymmetric Ni octahedral units linked by a bridging btc ligand halved by an inversion center. Each Ni cation coordinates two chelating \(\kappa^2 \text{N,N'amp}\) ligands, a bridging \(\mu_2 \kappa^2\text{O}_2\text{O'}\) btc and one coordinated water molecule. The complex formulation is completed by an extremely large number of water solvates, 5 independent molecules, 10 in all for each binuclear unit. Molecular bond distances and angles are featureless, and will not be discussed (Table 2 shows the rather regular coordination distances and angles in the Ni polyhedron).

These 1D substructures, in turn, “pierce” the (100) solvate network through the large (R\(^{20}\))(40) “square” holes, both substructures interacting strongly through H-bonds #13 to #17 in Table 3, defining a densely packed 3D structure.

The magnetic properties of [Ni\(_2\)\(\text{amp}\)\((\text{btc})(\text{H}_2\text{O})_2\)]\(\cdot\)10\(\text{H}_2\text{O}\) (I) were determined by magnetic susceptibility measurements performed as a function of temperature in the range 2 – 300 K. Figure 4 (a) shows a plot of \(\chi_M\) vs T, in the whole temperature range. The susceptibility data obeys the Curie Weiss law with a negative Weiss constant \(\theta = -1.81\) K. This value is indicative of weak antiferromagnetic interactions.

Figure 4 (b) shows the magnetic behaviour of complex (I) in the form of the thermal variation of the product \(\chi_M T\). This product is almost constant between 300 and 20 K, but it undergoes a sharp decrease at low temperatures indicating weak antiferromagnetic interactions between the paramagnetic centers.

![Fig. 1. The dinuclear unit in (I). (Displacement factors at a 50% level).](image)

The most interesting feature in the structure is the way in which the supra-molecular assembly is made up. The extremely large solvate part of the structure (O2W to O5W) conforms a dense, crooked 2D network parallel to (100), via H-bonds #1 to #6 in Table 3, made up by small (R\(^4\)) and large (R\(^{20}\)) rings (Fig. 2a and 2b).

On the other hand, the complexes interact with each other through the H-bonds having O1W, N11 and N12 as donors (#7 to #12 in Table 3), forming chains parallel to [100] (Figs 3a and 3b).

![Fig. 2. a) The (100) solvato net, projected along [100]. b) a Sideways view, showing the undulating character of the 2D substructure.](image)

The agreement factor, \(R = \sum(x_{\text{obs}} - x_{\text{cal}})^2/\sum(x_{\text{obs}})^2\) is 2.4 \(\cdot\) 10\(^{-5}\).

The small negative exchange coupling constant \(J\) is consistent with the long distance between both nickel ions (11.48 Å) and confirms the antiferromagnetic character of the compound.

In a magnetic study of Ni (II) centers in an octahedral environment with weak antiferromagnetic behavior, one parameter to be considered is the zero-field splitting (D) [18]. Results reported in the literature indicate sometimes that the inclusion of this term improves the quality of the magnetic fits but does not significantly alter the values of the exchange constant J or the calculated value of g. In this respect Prushan et al. [19] reported the synthesis and magnetic characterization of a dinuclear nickel (II) complex formulated as [Ni\(_2\)\(\text{dmap}\)\((\text{H}_2\text{O})_2\left(\text{ClO}_4\right)_{2}3\left(\text{CH}_3\right)\text{CO}\) (2) where \(\text{dmap}\) is 2-(2-pyridyl)methyl][methyl]amino[methyl]phenol. In this complex, two anionic \(\text{dmap}\) ligands bridge two Ni(II) centers via \(\mu_2\)-phenolate oxygen donor.
Both nickel(II) centers have distorted octahedral symmetry. The complex exhibited an antiferromagnetic behavior. The magnetic susceptibility data were adjusted to a model derived from Kambe’s method that includes the zero field splitting ($D = -1.6 \text{ cm}^{-1}$) giving values of $J = 0.85 \text{ cm}^{-1}$, $g = 2.26$. The authors indicate that, not including the term $D$ in the adjustment model, it results in almost identical values of $J$ and $g$ [19].

This result is similar to that found in the complexes $[\text{Ni}_2(\text{PMTA})\text{(bipy)}]_3$ (3) and $[\text{Ni}_3(\text{PMTA})\text{(phen)}]_4$ (4) informed by Li et al. [20] (where L denotes 2,2’-bipyridine (bpy), or 1,10-phenanthroline (phen) and PMTA is the tetra-anion of pyromellitic acid). The complexes have a dimeric structure where PMTA acts as a bridging ligand. The coordination environment around each nickel atom was described as distorted octahedral. Both complexes exhibited antiferromagnetic exchange interactions with $J = 0.98 \text{ cm}^{-1}$, $g = 2.18$ for (3) and $J = -1.16 \text{ cm}^{-1}$, $g = 2.14$ for (4). The authors indicated that, considering the zero-field splitting in the calculations, a much better fit of the experimental data was obtained, but the values of $J$ and $g$ remained essentially unchanged. The values obtained in this case were $J = -0.95 \text{ cm}^{-1}$, $g = 2.16$, $D = -1.9 \text{ cm}^{-1}$ for (3) and $J = -1.20 \text{ cm}^{-1}$, $g = 2.15$ and $D = -1.8 \text{ cm}^{-1}$ for (4).

4. Final remarks

There is scarce information in the literature regarding magnetic properties of Ni(II) complexes with carboxylate bridges similar to (1). In the complexes $[\text{Ni}_2(\text{PMTA})\text{(bipy)}]_3$ (3) and $[\text{Ni}_3(\text{PMTA})\text{(phen)}]_4$ (4) discussed above, the complexes presented weak magnetic coupling, with $J = -0.98 \text{ cm}^{-1}$ and $-1.16 \text{ cm}^{-1}$ respectively [20]. This type of behaviour was also observed in complexes with a dicarboxylic bridging, as $[\text{Ni}_2(\text{tp})(\text{pre})(\text{Him})\text{(ClO}_4)]_2$ (5) where pre$=1.3$-diaminopropane Him$=$ imidazole, tp$=$ terephthalate, reported by Xiao-Ming Chen and coworkers [21]. This complex consisted in two octahedral Ni(II) centers, 11.505Å apart and bridged by a tp diadonate where both carboxylates act as monodentate. The small interchange constant $J = 0.7 \text{ cm}^{-1}$ indicated a weak antiferromagnetic interaction.

Another example of this type is the $[\text{Ni}_4(\text{cch})(\mu-\text{TPHA})](\text{ClO}_4)_2$ (6) complex where cch is rac-5,7,7,12,14,14-hexamethyl-1,4,8,11-tetraazacyclotetradecane and TPHA is the dianion from terephthalic acid, reported by En Qing Gao et al. [22]. In this complex, the Ni(II) ions occupy distorted octahedral environments, linked by the carboxylate groups of the terephatic ligand, acting in a bidentate fashion. In this case, the complex was also antiferromagnetic, with an interchange constant $J = 0.33 \text{ cm}^{-1}$.

At first glance all these results would suggest that this type of bridging would not favor the magnetic interchange due to the unfavourably large interdimeric distances ($>10 \text{Å}$) but, on the other hand, Wieghardt and coworkers [23] have found in their studies of Cu(II) complexes that rather strong magnetic couplings may arise along large distances, through adequate orbital paths.

Thus, the behaviour is not clear and leaves the unavoidable conclusion that a thorough magneto-structural study in a $[\text{Ni}_4\text{btc}(\text{L})_4]$ homologous series is needed to better understand the magnetic phenomena in this type of complexes.

DATA AVAILABILITY

The data used to support the findings of this study are available from the corresponding author upon request.

CONFLICT OF INTEREST

The authors declare that there is no conflict of interest regarding the publication of this paper.
